Vision Transformation for Dense Prognosis

[1] N. Fathima Shrene Shifna

[1] Assistant Professor, Department of Computer Science and Engineering, Stella Mary's College of Engineering, India.

Abstract: To introduce dense vision transformers, an architecture that leverages vision transformers in place of convolutional networks as a backbone for dense prediction tasks. To as- semble tokens from various stages of the vision transformer into image-like representations at various resolutions and progressively combine them into full-resolution predictions using a convolutional decoder. The transformer backbone processes representations at a constant and relatively high resolution and has a global receptive field at every stage. These properties allow the dense vision transformer to pro- vide finer-grained and more globally coherent predictions when compared to fully-convolutional networks. This ex- periments show that this architecture yields substantial im- provements on dense prediction tasks, especially when a large amount of training data is available. For monocular depth estimation, we observe an improvement of up to 28% in relative performance when compared to a state-of-the- art fully-convolutional network. When applied to semantic segmentation, dense vision transformers set a new state of the art on ADE20K with 49.02% mIoU. We further show that the architecture can be fine-tuned on smaller datasets such as NYUv2, KITTI, and Pascal Context where it also sets the new state of the art.

INTRODUCTION

Virtually all existing architectures for dense prediction are based on convolutional networks [6, 31, 34, 42, 49, 50, 53]. The design of dense prediction architectures com- monly follows a pattern that logically separates the network into an encoder and a decoder. The encoder is frequently based on an image classification network, also called the backbone, that is pretrained on a large corpus such as Im- ageNet [9]. The decoder aggregates features from the en- coder and converts them to the final dense predictions. Architectural research on dense prediction frequently focuses

on the decoder and its aggregation strategy [6, 7, 50, 53]. However, it is widely recognized that the choice of back- bone architecture has a large influence on the capabilities of the overall model, as any information that is lost in the encoder is impossible to recover in the decoder.

Convolutional backbones progressively downsample the input image to extract features at multiple scales. Down- sampling enables a progressive increase of the receptive field, the grouping of low-level features into abstract high-level features, and simultaneously ensures that memory and computational requirements of the network remain tractable. However, downsampling has distinct drawbacks that are particularly salient in dense prediction tasks: fea- ture resolution and granularity are lost in the deeper stages of the model and can thus be hard to recover in the decoder. While feature resolution and granularity may not matter for some tasks, such as image classification, they are critical for dense prediction, where the architecture should ideally be able to resolve features at or close to the resolution of the input image.

Various techniques to mitigate the loss of feature gran- ularity have been proposed. These include training at higher input resolution (if the computational budget per- mits), dilated convolutions [49] to rapidly increase the re- ceptive field without downsampling, appropriately-placed skip connections from multiple stages of the encoder to the decoder [31], or, more recently, by connecting multi- resolution representations in parallel throughout the net- work [42]. While these techniques can significantly im- prove prediction quality, the networks are still bottlenecked by their fundamental building block: the convolution. Con- volutions together with non-linearities form the fundamen- tal computational unit of image analysis networks. Convo- lutions, by definition, are linear operators that have a lim- ited receptive field. The limited receptive field and the lim- ited expressivity of an individual convolution necessitate se- quential stacking into very deep architectures to acquire suf- ficiently broad context and sufficiently high representational power. This, however, requires the production of many in- termediate representations that require a large amount of memory. Downsampling the intermediate representations is necessary to keep memory consumption at levels that are feasible with existing computer architectures.

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

In this work, we introduce the dense prediction trans- former (DPT). DPT is a dense prediction architecture that is based on an encoder-decoder design that leverages a trans- former as the basic computational building block of the en- coder. Specifically, we use the recently proposed vision transformer (ViT) [11] as a backbone architecture. We re- assemble the bag-of-words representation that is provided by ViT into image-like feature representations at various resolutions and progressively combine the feature repre- sentations into the final dense prediction using a convolu- tional decoder. Unlike fully-convolutional networks, the vi- sion transformer backbone foregoes explicit downsampling operations after an initial image embedding has been com- puted and maintains a representation with constant dimen- sionality throughout all processing stages. It furthermore has a global receptive field at every stage. We show that these properties are especially advantageous for dense pre- diction tasks as they naturally lead to fine-grained and glob- ally coherent predictions.

I conduct experiments on monocular depth estimation and semantic segmentation. For the task of general-purpose monocular depth estimation [30], where large-scale train- ing data is available, DPT provides a performance increase of more than 28% when compared to the top-performing fully-convolutional network for this task. The architecture can also be fine-tuned to small monocular depth prediction datasets, such as NYUv2 [35] and KITTI [15], where it also sets the new state of the art. We provide further evi- dence of the strong performance of DPT using experiments on semantics segmentation. For this task, DPT sets a new state of the art on the challenging ADE20K [54] and Pas- cal Context [26] datasets. Our qualitative results indicate that the improvements can be attributed to finer-grained and more globally coherent predictions in comparison to convolutional networks.

2. Related Work

Fully-convolutional networks [33, 34] are the prototyp- ical architecture for dense prediction. Many variants of this basic pattern have been proposed over the years, how- ever, all existing architectures adopt convolution and sub- sampling as their fundamental elements in order to learn multi-scale representations that can leverage an appropri- ately large context. Several works propose to progressively upsample representations that have been pooled at differ- ent stages [1, 23, 27, 31], while others use dilated convo-

lutions [6, 7, 49] or parallel multi-scale feature aggregation at multiple scales [53] to recover fine-grained predictions while at the same time ensuring a sufficiently large context. More recent architectures maintain a high-resolution repre-

sentation together with multiple lower-resolution representations throughout the network [37, 42].

Attention-based models [2] and in particular transform- ers [39] have been the architecture of choice for learning strong models for natural language processing (NLP) [4, 10, 24] in recent years. Transformers are set-to-set mod- els that are based on the self-attention mechanism. Trans- former models have been particularly successful when in- stantiated as high-capacity architectures and trained on very large datasets. There have been several works that adapt at- tention mechanisms to image analysis [3, 28, 29, 41, 52]. In particular, it has recently been demonstrated that a direct ap- plication of token-based transformer architectures that have been successful in NLP can yield competitive performance on image classification [11]. A key insight of this work was that, like transformer models in NLP, vision transformers need to be paired with a sufficient amount of training data to realize their potential.

3. Architecture

This section introduces the dense vision transformer. We maintain the overall encoder-decoder structure that has been successful for dense prediction in the past. We leverage vi- sion transformers [11] as the backbone, show how the rep- resentation that is produced by this encoder can be effect tively transformed into dense predictions, and provide in- tuition for the success of this strategy. An overview of the complete architecture is shown in Figure 1 (left).

Transformer encoder. On a high level, the vision trans- former (ViT) [11] operates on a bag-of-words representation of the image [36]. Image patches that are individually embedded into a feature space, or alternatively deep features extracted from the image, take the role of "words". I will refer to embedded "words" as tokens throughout the rest of this work. Transformers transform the set of to-kens using sequential blocks of multi-headed self-attention (MHSA) [39], which relate tokens to each

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

other to trans- form the representation.

Importantly for our application, a transformer maintains the number of tokens throughout all computations. Since to- kens have a one-to-one correspondence with image patches, this means that the ViT encoder maintains the spatial reso- lution of the initial embedding throughout all transformer stages. Additionally, MHSA is an inherently global oper- ation, as every token can attend to and thus influence ev- ery other token. Consequently, the transformer has a global receptive field at every stage after the initial embedding. This is in stark contrast to convolutional networks, which progressively increase their receptive field as features pass through consecutive convolution and downsampling layers. More specifically, ViT extracts a patch embedding from the image by processing all non-overlapping square patches

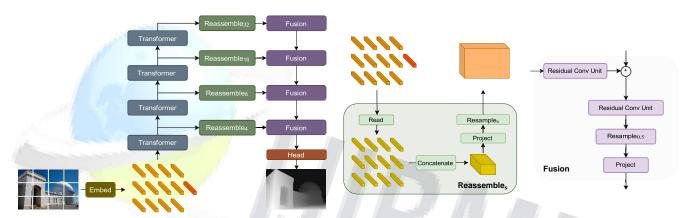

Figure 1. Left: Architecture overview. The input image is transformed into tokens (orange) either by extracting non-overlapping patches followed by a linear projection of their flattened representation (DPT-Base and DPT-Large) or by applying a ResNet-50 feature extractor (DPT-Hybrid). The image embedding is augmented with a positional embedding and a patch-independent readout token (red) is added. The tokens are passed through multiple transformer stages. We reassemble tokens from different stages into an image-like representation at multiple resolutions (green). Fusion modules (purple) progressively fuse and upsample the representations to generate a fine-grained

prediction. Center: Overview of the Reassembles operation. Tokens are assembled into feature maps with 1 the spatial resolution of the input image. Right: Fusion blocks combine features using residual convolutional units [23] and upsample the feature maps. of size p2 pixels from the image. The patches are flattened into vectors and individually embedded using a linear pro-jection. An alternative, more sample-efficient, variant of ViT extracts the embedding by applying a ResNet50 [16] to the image and uses the pixel features of the resulting feature maps as tokens. Since transformers are set-to-set functions, they do not intrinsically retain the information of the spatial positions of individual tokens. The image embeddings are thus concatenated with a learnable position embedding to add this information to the representation. Following work in NLP, the ViT additionally adds a special token that is not grounded in the input image and serves as the final, global image representation which is used for classification. We refer to this special token as the readout token. The result of applying the embedding procedure to an image of size $H \times W$ pixels is a a set of $t^0 = \{t^0, \ldots, t^0\}$, $t^0 \in \mathbb{R}^D$ tokens, where $N_p = \frac{HW}{V}$, t_0 refers to the readout token, and D is the feature dimension of each token.

The input tokens are transformed using L transformer layers into new representations tl, where l refers to the out- put of the l-th transformer layer. Dosovitskiy et al. [11] define several variants of this basic blueprint. To use three variants in our work: ViT-Base, which uses the patch-based embedding procedure and features 12 transformer layers; ViT-Large, which uses the same embedding procedure and has 24 transformer layers and a wider feature size D; and ViT-Hybrid, which employs a ResNet50 to compute the im- age embedding followed by 12 transformer layers. We use patch size p = 16 for all experiments. To refer the inter- ested reader to the original work [11] for additional details on these

patch size p = 16 for all experiments. To refer the inter- ested reader to the original work [11] for additional details on these architectures.

The embedding procedure for ViT-Base and ViT-Large projects the flattened patches to dimension D = 768 and D = 1024, respectively. Since both feature dimensions are larger than the number of pixels in an input patch, this means that the embedding procedure can learn to retain in-formation if it is beneficial for the task. Features from the input patches can in principle be resolved with pixel-level accuracy. Similarly, the ViT-Hybrid architecture extracts features at 1 the input resolution, which is twice as high as the lowest-resolution features that are commonly used with convolutional backbones.

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

Convolutional decoder. Our decoder assembles the set of tokens into image-like feature representations at various resolutions. The feature representations are progressively fused into the final dense prediction. To propose a sim- ple three-stage Reassemble operation to recover image-like the transformer encoder:

Reassemble $P(t) = (Resample \circ Concatenate \circ Read)(t)$.

resentation with respect to the input image, and D[^] denotes where s denotes the output size ratio of the recovered rep- the output feature dimension.

Initially map the Np + 1 tokens to a set of Np tokens that is amenable to spatial concatenation into an image-like

representation:

Read:
$$R^{N_p+1\times D} \to R^{N_p\times D}$$
. (1)

This operation is essentially responsible for appropriately

handling the readout token. Since the readout token doesn't serve a clear purpose for the task of dense prediction, but could potentially still be useful to capture and distribute

global information, we evaluate three different variants of this mapping:

$$Read_{ignore}(t) = \{t_1, \dots, t_{N_0}\}$$
 (2)

Read_{add}
$$(t) = \{t_1 + t_0, \dots, t_{N_p} + t_0\}$$
 (3)

passes the information from the readout token to another, Read_{proj} $(t) = \{\text{mlp}(\text{cat}(t_1, t_0)), \dots \text{tokens by adding the representations,}\}$

$$mlp(cat(t_{N_D}, t_0))$$
 (4)

readout to all other tokens before projecting the representation to the original feature dimension D using a linear layer followed by a GELU non-linearity [17].

After a Read block, the resulting Np tokens can be re-shaped into an image-like representation by placing each token according to the position of the initial patch in the image. Formally, we apply a spatial concatenation operation that results in a feature map of size $\frac{H}{N} \times \frac{W}{N}$ with D

channels:

<u>H</u> <u>W</u>

Concatenate:
$$R^{N_p \times D} \rightarrow R^{p \times p \times D}$$
. (5)

Finally pass this representation to a spatial resampling layer that scales the representation to size $\underline{H} \times \underline{W}$ with \hat{D} features per pixel:

<u>HW DĤ Ŵ</u>D

Resample_s:
$$R^{p \times p \times} \rightarrow R^{s \times s \times}$$
. (6)

To implement this operation by first using 1 1 convolutions to project the input representation to D $^{\circ}$, followed by a (strided) 3 3 convolution when s p, or a strided 3 3 transpose convolution when s < p, to implement spatial downsampling and upsampling operations, respectively. Irrespective of the exact transformer backbone, we re- assemble features at four different stages and four different resolutions. To assemble features from deeper layers of the transformer at lower resolution, whereas fea- tures from early layers are assembled at higher resolution. When using ViT-Large, we reassemble tokens from layers 1 = 5, 12, 18, 24, whereas with ViT-Base we use layers 1 = 3, 6, 9, 12. We use features from the first and sec- 1 = 9, 12 when using ViT-Hybrid. Our default architectord ResNet block from the embedding network and stages ture uses projection as the readout operation and produces

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

feature maps with $\hat{D}=256$ dimensions. We will refer to these architectures as DPT-Base, DPT-Large, and DPT- Hybrid, respectively. Finally combine the extracted feature maps from consecutive stages using a RefineNet-based feature fusion block [23, 45] (see Figure 1 (right)) and progressively up- sample the representation by a factor of two in each fusion stage. The final representation size has half the resolution of the input image. To attach a task-specific output head to produce the final prediction. A schematic overview of the complete architecture is shown in Figure 1.

Handling varying image sizes. Akin to fully-convolutional networks, DPT can handle varying image sizes. As long as the image size is divisible by p, the embedding procedure can be applied and will produce a varying number of im- age tokens Np. As a set-to-set architecture, the transformer encoder can trivially handle a varying number of tokens. However, the position embedding has a dependency on the image size as it encodes the locations of the patches in the input image. To follow the approach proposed in [11] and linearly interpolate the position embeddings to the appro- priate size. Note that this can be done on the fly for every image. After the embedding procedure and the transformer stages, both the reassemble and fusion modules can triv- ially handle a varying number of tokens, provided that the input image is aligned to the stride of the convolutional de- coder (32 pixels).

4. Experiments

To apply DPT to two dense prediction tasks: monoc- ular depth estimation and semantic segmentation. For both tasks, we show that DPT can significantly improve accuracy when compared to convolutional networks with a similar capacity, especially if a large training dataset is available. I first present our main results using the default configuration and show comprehensive ablations of different DPT configurations at the end of this section

4.1. Monocular Depth Estimation

Monocular depth estimation is typically cast as a dense regression problem. It has been shown that massive meta- datasets can be constructed from existing sources of data, provided that some care is taken in how different representations of depth are unified into a common representation and that common ambiguities (such as scale ambiguity) are appropriately handled in the training loss [30]. Since trans- formers are known to realize their full potential only when an abundance of training data is available, monocular depth estimation is an ideal task to test the capabilities of DPT. Experimental protocol. Closely follow the protocol of Ranftl et al. [30]. To learn a monocular depth prediction network using a scale- and shift-invariant trimmed loss that operates on an inverse depth representation, together with the gradient-matching loss proposed in [22]. To construct a meta-dataset that includes the original datasets that were used in [30] (referred to as MIX 5 in that work) and extend it with with five additional datasets ([18, 43, 44, 46, 47]).

		WHDR	AbsRel	AbsRel	<i>δ</i> >1.25	<i>δ</i> >1.25	<i>δ</i> >1.25

Table 1. Comparison to the state of the art on monocular depth estimation. We evaluate zero-shot cross-dataset transfer according to the protocol defined in [30]. Relative performance is computed with respect to the original MiDaS model [30]. Lower is better for all metrics.

I refer to this meta-dataset as MIX 6. It contains about 1.4 million images and is, to the best of our knowledge, the largest training set for monocular depth estimation that has ever been compiled. Adam [19] and set a learning rate of 1e 5 for the back-bone and 1e 4 for the decoder weights. The encoder is to use multi-objective optimization [32] together with initialized with ImageNet-pretrained weights, whereas the decoder is initialized randomly. We use an output head that consists of 3 convolutional layers. The output head progres- sively halves the feature dimension and upsamples the pre- dictions to the input resolution after the first convolutional layer (details in supplementary material). We disable batch normalization in the decoder, as we found it to negatively such epoch consists of 72,000 steps that the longer side is 384 pixels and train on random square crops of size 384. We train for 60

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

epochs, where one influence results for regression tasks. We resize the image with a batch size of 16. As the batch size is not divisible by the number of datasets, to construct a mini-batch by first drawing datasets uniformly at random before sampling from the respective datasets. Perform random horizontal flips for data augmentation. Similar to [30], we first pretrain on a well-curated subset of the data [45, 46, 47] for 60 epochs before training on the full dataset.

Table 3. Evaluation on KITTI (Eigen split).

Zero-shot cross-dataset transfer.

Table 1 shows the re- sults of zero-shot transfer to different datasets that were not seen during training. We refer the interested reader to Ran- ftl et al. [30] for details of the evaluation procedure and error metrics. For all metrics, lower is better. Both DPT variants significantly outperform the state of the art. The average relative improvement over the best published architecture, MiDaS, is more than 23% for DPT-Hybrid and 28% for DPT-Large. DPT-Hybrid achieves this with a comparable network capacity (Table 9), while DPT-Large is about 3 times larger than MiDaS. Note that both architectures have similar latency to MiDaS (Table 9).

To ensure that the observed improvements are not only due to the enlarged training set, we retrain the fully-convolutional network used by MiDaS on our larger meta- dataset MIX 6. While the fully-convolutional network in- deed benefits from the larger training set, we observe that both DPT variants still strongly outperform this network. This shows that DPT can better benefit from increased train- ing set size, an observation that matches previous findings on transformer-based architectures in other fields.

The quantitative results are supported by visual com- parisons in Figure 2. DPT can better reconstruct fine de- tails while also improving global coherence in areas that are challenging for the convolutional architecture (for example, large homogeneous regions or relative depth arrangement across the image).

Fine-tuning on small datasets.

Fine-tune DPT-Hybrid on the KITTI [15] and NYUv2 [35] datasets to further com- pare the representational power of DPT to existing work. Since the network was trained with an affine-invariant loss, its predictions are arbitrarily scaled and shifted and can have large magnitudes. Direct fine-tuning would thus be chal- lenging, as the global mismatch in the magnitude of the predictions to the ground truth would dominate the loss. Thus first align predictions of the initial network to each training sample using the robust alignment procedure de- scribed in [30]. We then average the resulting scales and shifts across the training set and apply the average scale and shift to the predictions before passing the result to the loss. Make fine-tune with the loss proposed by Eigen et al. [12]. To disable the gradient-matching loss for KITTI since this dataset only provides sparse ground truth.

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

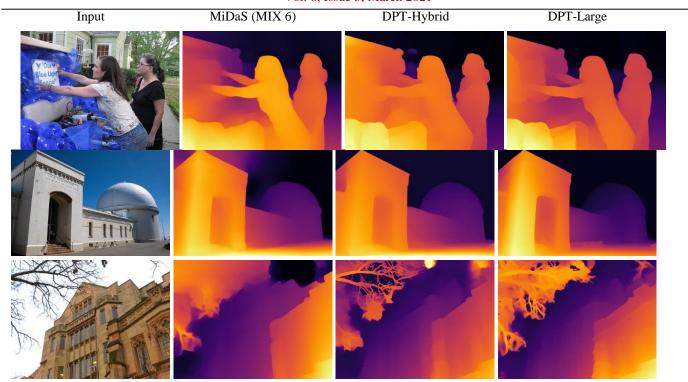

Figure 2. Sample results for monocular depth estimation. Compared to the fully-convolutional network used by MiDaS, DPT shows better global coherence (e.g., sky, second row) and finer-grained details (e.g., tree branches, last row).

shift to the predictions before passing the result to the loss. Make fine-tune with the loss proposed by Eigen et al. [12]. To disable the gradient-matching loss for KITTI since this dataset only provides sparse ground truth.

Tables 2 and 3 summarize the results. Our architecture matches or improves state-of-the-art performance on both datasets in all metrics. This indicates that DPT can also be usefully applied to smaller datasets.

4.2. Semantic Segmentation

To choose semantic segmentation as our second task since it is representative of discrete labeling tasks and is a very competitive proving ground for dense prediction ar- chitectures. To employ the same backbone and decoder structure as in previous experiments. We use an output head that predicts at half resolution and upsamples the logits to full resolution using bilinear interpolation (details in sup- plementary material). The encoder is again initialized from ImageNet-pretrained weights, and the decoder is initialized randomly.

Experimental protocol. In order to closely follow the protocol es- tablished by Zhang et al. [51]. We employ a cross-entropy loss and add an auxiliary output head together with an aux- iliary loss to the output of the penultimate fusion layer. Fix the weight of the auxiliary loss as 0.2. Dropout with a rate of 0.1 is used before the final classification layer in both heads. We use SGD with momentum 0.9 and a poly- nomial learning rate scheduler with decay factor 0.9. We use batch normalization in the fusion layers and train with batch size 48. Images are resized to 520 pixels side length, the range (0.5, 2.0) for data augmentation. We train on square random crops of size 480. Make the learning rate to We use random horizontal flipping and random rescaling in 0.002. To use multi-scale inference at test time and report

both pixel accuracy (pixAcc) as well as mean Intersection- over-Union (mIoU). mentation dataset [54] for 240 epochs. Table 4 summa- ADE20K. We train the DPT on the **ADE20K** semantic seg- rizes our results on the validation set. DPT-Hybrid outper forms all existing fully-convolutional architectures. DPT- Large performs slightly worse, likely because of the sig- nificantly smaller dataset compared to our previous experi- ments. Figure 3 provides visual comparisons. We observe that the DPT tends to produce cleaner and finer-grained de- lineations of object boundaries and that the predictions are also in some cases less cluttered.

Fine-tuning on smaller datasets. Fine-tune DPT- Hybrid on the Pascal Context dataset [26] for 50 epochs. All other hyper-parameters remain the same. Table 5 shows re- sults on the validation set for this experiment. We again see that DPT can provide strong performance even on smaller datasets.

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

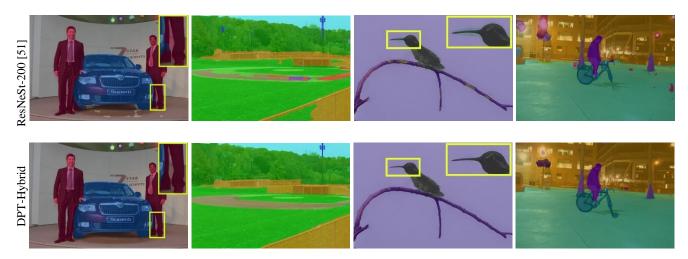

Figure 3. Sample results for semantic segmentation on ADE20K (first and second column) and Pascal Context (third and fourth column). Predictions are frequently better aligned to object edges and less cluttered.

4.3 Ablations

To examine a number of aspects and technical choices in DPT via ablation studies. We choose monocular depth esti- mation as the task for our ablations and follow the same pro- tocol and hyper-parameter settings as previously described. To use a reduced meta-dataset that is composed of three datasets [45, 46, 47] and consists of about 41,000 images.

To choose these dataset since they provide high quality. To split each dataset into a training set and point's results on the validation set in terms of relative solute deviation after affine alignment of the predictions to the ground truth [30]. Unless specified otherwise, we use ViT-Base as the backbone architecture.

Skip connections. Convolutional architectures offer natu- ral points of interest for passing features from the encoder to the decoder, namely before or after downsampling of the

	Backbone		pixAcc [%]	mIoU [%]

representation. Since the transformer backbone maintains a constant feature resolution, it is not clear at which points in the backbone features should be tapped. We evaluate sev- eral possible choices in Table 6 (top). We observe that it is beneficial to tap features from layers that contain low-level features as well as deeper layers that contain higher-level features. To adopt the best setting for all further experi- ments.

To perform a similar experiment with the hybrid archi- tecture in Table 6 (bottom), where R0 and R1 refer to us- ing features from the first and second downsampling stages of the ResNet50 embedding network. We observe that us- ing low-level features from the embedding network leads to better performance than using features solely from the transformer stages. We use this setting for all

International Journal of Innovative Research in Management, Engineering, and Technology Vol. 6, Issue 3, March 2021

further exper- iments that involve the hybrid architecture.

Readout token. Table 7 examines various choices for im- plementing the first stage of the Reassemble block to han- dle the readout token. While ignoring the token yields good performance, projection provides slightly better per- formance on average. Adding the token, on the other hand, yields worse performance than simply ignoring it. We use projection for all further experiments.

Backbones. The performance of different backbones is

shown in Table 8. ViT-Large outperforms all other back- bones but is also almost three times larger than ViT-Base and ViT-Hybrid. ViT-Hybrid outperforms ViT-Base with a similar number of parameters and has comparable perfor- mance to the large backbone. As such it provides a good trade-off between accuracy and capacity.

ViT-Base has comparable performance to ResNext101- WSL, while ViT-Hybrid and ViT-Large improve perfor- mance even though they have been pretrained on signifi- cantly less data. Note that ResNext101-WSL was pretrained on a billion-scale corpus of weakly supervised data [25] in addition to ImageNet pretraining. It has been observed that this pretraining boosts the performance of monocular depth prediction [30]. This architecture corresponds to the origi- nal MiDaS architecture.

Finally compare to a recent variant of ViT called DeIT [38]. DeIT trains the ViT architecture with a more data-efficient pretraining procedure. Note that the DeIT- Base architecture is identical to ViT-Base, while DeIT- Base-Dist introduces an additional distillation token, which we ignore in the Reassemble operation. We observe that DeIT-Base-Dist indeed improves performance when com- pared to ViT-Base. This indicates that similarly to convolutional architectures, improvements in pretraining procedures for image classification can benefit dense prediction tasks.

Inference resolution. While fully-convolutional architec- tures can have large effective receptive fields in their deepest layers, the layers close to the input are local and have small receptive fields. Performance thus suffers heavily when performing inference at an input resolution that is signifi- cantly different from the training resolution. Transformer encoders, on the other hand, have a global receptive field

	HRWSI	BlendedMVS	ReDWeb	Mean
ResNet50	0.0890	0.0887	0.1029	0.0935
ResNext101-WSL	0.0780	0.0751	0.0886	0.0806
DeIT-Base	0.0798	0.0804	0.0925	0.0842
DeIT-Base-Dist	0.0758	0.0758	0.0871	0.0796
ViT-Base	0.0797	0.0764	0.0895	0.0819
ViT-Large	0.0740	0.0747	0.0846	0.0778
ViT-Hybrid	0.0738	0.0746	0.0864	0.0783

Table 8. Ablation of backbones. The hybrid and large backbones consistently outperform the convolutional baselines. The base architecture can outperform the convolutional baseline with better pretraining (DeIT-Base-Dist).

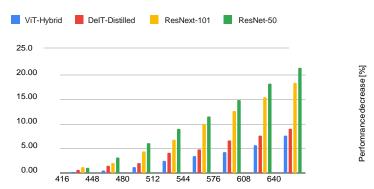

Figure 4. Relative loss in performance for different inference res- olutions (lower is better).

in every layer. We conjecture that this makes DPT less de-pendent on inference resolution. To test this hypothesis, we plot the loss in performance of different architectures when performing inference at resolutions higher than the training resolution of 384 384 pixels. To plot the relative decrease in performance in percent with respect to the performance of performing inference at the training resolution in Fig- ure 4. To observe that the performance of DPT variants indeed degrades more gracefully as inference resolution in- creases.

Inference speed. Table 9 shows inference time for differ- ent network architectures. Timings were conducted on an Intel Xeon Platinum 8280 CPU @ 2.70GHz with 8 physical cores and an Nvidia RTX 2080 GPU. We use square images with a width of 384 pixels and report the average over 400 runs. DPT-Hybrid and DPT-Large show comparable latency to the fully-convolutional architecture used by MiDaS. In-terestingly, while DPT-Large is substantially larger than the other architectures in terms of parameter count, it has competitive latency since it exposes a high degree of parallelism through its wide and comparatively shallow structure

Parameters [million]	105	112	123	343
Time [ms] 32	17	38	35	

Table 9. Model statistics. DPT has comparable inference speed to the state of the art.

.5. Conclusion

I have introduced the dense prediction transformer, DPT, a neural network architecture that effectively leverages vision transformers for dense prediction tasks. Our experiments on monocular depth estimation and semantic segmentation show that the presented architecture produces more fine-grained and globally coherent predictions when compared to fully-convolutional architectures. Similar to prior work on transformers, DPT unfolds its full potential when trained on large-scale datasets.
